## 1. Memory Problems

- Not enough memory
- Holes in address space
- Programs overwriting

## 2. What is Virtual Memory?

- Layer of indirection
- How does indirection solve above
- Page tables and translation

## 3. How do we implement VM?

- Create and store page tables
- Fast address translation

## 4. Virtual Memory and Caches

- Prevent cache performance degradation when using VM

**A:** 1 for each Word...  $2^{30}$  [1 billion entries]

Memory is word-aligned and we need to access every word. That's a total of 1GB just for this table!

Illustration from the textbook

**FIGURE 5.28** The page table maps each page in virtual memory to either a page in main memory or a page stored on disk, which is the next level in the hierarchy. The virtual page number is used to index the page table. If the valid bit is on, the page table supplies the physical page number (i.e., the starting address of the page in memory) corresponding to the virtual page. If the valid bit is off, the page currently resides only on disk, at a specified disk address. In many systems, the table of physical page addresses and disk page addresses, while logically one table, is stored in two separate data structures. Dual tables are justified in part because we must keep the disk addresses of all the pages, even if they are currently in main memory. Remember that the pages in main memory and the pages on disk are the same size.

**A:**  $2^{20}$  [1 million]

We need to address  $2^{32}$  Bytes total but we partition pages into  $2^{12}$  (4 kB) chunks. By simple division we need  $2^{20}$ , or 1 million entries.

Illustration from the textbook

**FIGURE 5.26 Mapping from a virtual to a physical address.** The page size is  $2^{12} = 4$  KiB. The number of physical pages allowed in memory is  $2^{18}$ , since the physical page number has 18 bits in it. Thus, main memory can have at most 1 GiB, while the virtual address space is 4 GiB.

# Quincy Flint

## Illustration from the textbook

**FIGURE 5.27 The page table is indexed with the virtual page number to obtain the corresponding portion of the physical address.** We assume a 32-bit address. The page table pointer gives the starting address of the page table. In this figure, the page size is  $2^{12}$  bytes, or 4 KiB. The virtual address space is  $2^{32}$  bytes, or 4 GiB, and the physical address space is  $2^{30}$  bytes, which allows main memory of up to 1 GiB. The number of entries in the page table is  $2^{20}$ , or 1 million entries. The valid bit for each entry indicates whether the mapping is legal. If it is off, then the page is not present in memory. Although the page table entry shown here need only be 19 bits wide, it would typically be rounded up to 32 bits for ease of indexing. The extra bits would be used to store additional information that needs to be kept on a per-page basis, such as protection.

**A:** 16

We need 16 bits to index every Word in a Page. This means my *Virtual Page Number* is now *16 bits* (32-16) and my *Physical Page Number* is *12 bits* (28-16).

Illustration from the textbook

**FIGURE 5.29** The TLB acts as a cache of the page table for the entries that map to physical pages only. The TLB contains a subset of the virtual-to-physical page mappings that are in the page table. The TLB mappings are shown in color. Because the TLB is a cache, it must have a tag field. If there is no matching entry in the TLB for a page, the page table must be examined. The page table either supplies a physical page number for the page (which can then be used to build a TLB entry) or indicates that the page resides on disk, in which case a page fault occurs. Since the page table has an entry for every virtual page, no tag field is needed; in other words, unlike a TLB, a page table is *not* a cache.
